**Barriers to the implementation of k-anonymity
and related microdata anonymization techniques
in a realworld application**

Andreas Wiegand, 1878334
Ludwig Schallner, 1850413

1 Introduction

Nowadays data is a key factor in nearly every domain. It is comparable to the gold rush of the 19. century [9]. Furthermore, storage space and network connectivity become affordable [11]. But to use the data for commercial or scientific purposes the privacy of the data holder does not have to be compromised or in other words the data holder need to know how to produce anonymous data otherwise the database cannot survive, because if the information of the table gets released there will be no need anymore for this data [11].

The papers The so-called k-anonymity method, which produces anonymous data, theoretical. But there are practical barriers that will occur in the real world. Those prevent such implementation. The goal of k-anonymity is, to prevent the possibility to get information about the real individual, or at least with k other possible individuals. So if a individual is described by a tuple of $\langle f_1, \dots, f_n \rangle$ features and each feature can have $\langle a_1, \dots, a_n \rangle$ attributes. There are at least k another individual with the same attribute for each feature so that there is no possibility to reduce the real individual and there will be at least k individuals with the same tuple[11].

The attributes that are used to link the external data is called quasi-identifiers. Typical values for them are gender, date of birth and zip code [7]. We will present techniques that override k-anonymity and get the real individual. Another problem we will introduce is, that the producing of k-anonymity of a computational view is an NP-hard problem, like Meyerson and Williams shown. ...

2 Basics

Microdata:

First of all, it should be clear what microdata is, those data is containing records of information about individuals. The upside versus the more known summary or aggregate data is, that microdata is naturally flexible. Everyone who has this data can perform own statistics from that data [1].

Identifier:

Identifier Definition

Quasi-identifier:

Even though explicit identifier got removed from published data. Such an explicit attribute, which would not uniquely identify the record owner. But if combined (with other non-explicit attributes), they become explicit identifier. Which resulting that those can link towards the owner. In such a case those attributes are called quasi-identifier [3]. Such process is shown in figure 1.

Sensitive data:

Sensitive Data Definition

Background knowledge:

Definition

K-Anonymity

3 Implementing of k-anonymity

Like Dalenius already mentioned it is absolutely necessary that an attacker, under no circumstances, can learn about whatsoever target if he is studying the published database. Not even if the attacker has background knowledge from any other sources [2]. Unfortunately like Dwork showed 2006 that such safety is impossible because of background knowledge. For example, if the attacker knows that Bob get paid twice as the average German man and the attacker got access to a database which publishes the average income by German men. The anonymity of Bob is compromised even if Bob's data is not in the database [4].

3.1 Linking data

A barrier to do the implementation of k-anonymity, the attacker can take another dataset and link both together to get rid off the k-anonymity and infer the real individual. This process is called linking data and was first described by Sweeney[11]. She showed that with a example of health care data from 37 states in the USA. The institute from which she bought the data, insures the anonymity of the individuals. Sweeney purchased the voter registration list for Cambridge Massachusetts and received information of the voters including ZIP code, birth date and gender (non explicit identifier) of each voter. She linked that information with the medical data. It was possible to deanonymize the data and

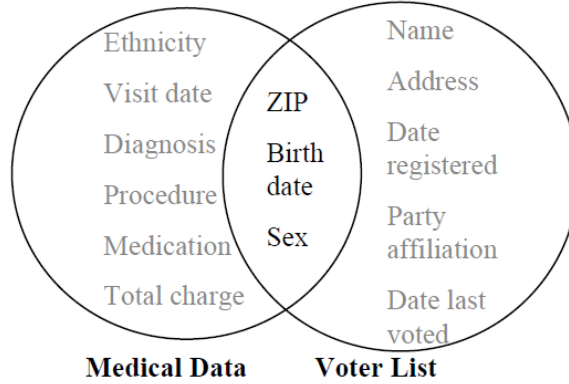

Fig. 1. linking data

get ethnicity, visit date, diagnosis, procedure, medication and total charge of some patients [11].

You got two datasets A and B. Each dataset got $\langle f_1, \dots, f_n \rangle$ features and $\langle r_1, \dots, r_n \rangle$ rows. Each row is then a tuple r_i with n features $\langle f_1, \dots, f_n \rangle$ describing the individual. Even tho the data is k-anonymized you can get rid of the anonymity of the individual by linking the A to B. So if $A \cap B \neq \emptyset$ it is possible to infer the anonymized individual [11]. As a result any attacker who knows such data (ZIP Code, Birth date and sex) could easily identify with such an attack his victim. For example Peter sees his ex-wife at the doctor, most likely he knows her ZIP-Code, Birth date and sex. Therefore he finds out what she is suffering from.

3.2 Unsorted matching attack against k-anonymity

There is a possibility of a leak of information, if the released k-anonymity data is in some kind of a sort release. This means the numerical attributes are descending or ascending sorted and attributes, which are of characters are alphabetical ordered, can give the attacker information about the sensitive data. To prevent this attack, just get the data into a random order with a pseudo randomized sorting algorithm [11]. As an example take a look at the table 3: matching attack will give an example on that. If you compare the different released generalized tables you can figure out all quasi identifiers of those [11].

...

3.3 Complexity of producing k-anonymity

Till now we only looked at problems of information leaking and privacy problems for individuals. Data is personal-specific information which is structured as a table in rows and columns. Rows are a tuple. The columns are attributes with

Table 1. matching attack

Age	ZIP
2	91058
4	91058

are a set of values which describe the certain attribute. A tuple specify a person. K-anonymity is about protecting the identity of a person not relationships of companies or governments. So the goal of k-anonymity is, not getting more information by linking the data to external data. The bridge between the data and external data is called "quasi-identifier". Examples for that would be ZIP, gender, birth date etc..

Generalization mean, replacing a value with a less specific but semantic identical value. For example we got a list of forenames of buys, (Achmed, Achilles, Achim). To generalize this names you can just (Ach*,Ach*, Ach*) delete the last chars of the name. So there is a less specific domain and now more generalize through this mapping. Suppression on the other hand means not releasing the value at all.
